Mycobacterium avium-Mycobacterium intracellular has been recognized as the causative organism of a wide range of disease conditions in both immunocompromised and immunocompetent patients. The infection by M. avium and M. intracellulare may take the form of subacute, chronic, or acute pulmonary disease (Legionnaires' disease), disseminated disease, and AIDS-related disease in which the organism is often found in lymph nodes, bone marrow, liver, and spleen. Mycobacterium avium is an important pathogen in the treatment of AIDS and lung transplant patients and is a significant factor in granulomatous infections in sarcoidosis and pigmented lung disease. See Walker, Jr., J. Clinical Pathology, 26:25 (1984); and Bentler, J. Bacteriology, 143:584-597 (1982). The diagnosis of M. avium infection is based on the isolation and identification of the organism in clinical specimens. Culturing M. avium is a tedious, slow process that requires special media and incubation conditions. As a result of the long incubation time and low yield, the diagnostic results are not generally available before one or two weeks after the specimen is received. The isolation of M. avium from clinical specimens may be very difficult and, in addition, a number of unrelated organisms, including other mycobacteria and many other bacteria may be isolated. For this reason, bacterial isolates are routinely tested for M. avium organisms using standard biochemical tests. This is a tedious and time consuming process that may require at least several days of incubation. Serological assays to detect antibodies against M. avium, including complement fixation, complement fixation inhibition, enzyme 2d92ce491b
